US009356885B2

(12) **United States Patent**
Aybay

(10) **Patent No.: US 9,356,885 B2**
(45) **Date of Patent: *May 31, 2016**

(54) **METHODS AND APPARATUS RELATED TO A DISTRIBUTED SWITCH FABRIC**

(71) Applicant: **Juniper Networks, Inc.**, Sunnyvale, CA (US)

(72) Inventor: **Gunes Aybay**, Los Altos, CA (US)

(73) Assignee: **Juniper Networks, Inc.**, Sunnyvale, CA (US)

(*) Notice: Subject to any disclaimer, the term of this patent is extended or adjusted under 35 U.S.C. 154(b) by 0 days.

This patent is subject to a terminal disclaimer.

(21) Appl. No.: **14/610,143**

(22) Filed: **Jan. 30, 2015**

(65) **Prior Publication Data**

US 2015/0139222 A1 May 21, 2015

Related U.S. Application Data

(63) Continuation of application No. 12/607,162, filed on Oct. 28, 2009, now Pat. No. 8,953,603.

(57) **ABSTRACT**

A method of sending data to a switch fabric includes assigning a destination port of an output module to a data packet based on at least one field in a first header of the data packet. A module associated with a first stage of the switch fabric is selected based on at least one field in the first header. A second header is appended to the data packet. The second header includes an identifier associated with the destination port of the output module. The data packet is sent to the module associated with the first stage. The module associated with the first stage is configured to send the data packet to a module associated with a second stage of the switch fabric based on the second header.

METHODS AND APPARATUS RELATED TO A DISTRIBUTED SWITCH FABRIC

This application is a continuation application of U.S. patent application Ser. No. 12/607,162, filed Oct. 28, 2009 and entitled "Methods and Apparatus Related to a Distributed Switch Fabric, the disclosure of which is hereby incorporated by reference in its entirety.

BACKGROUND

Embodiments described herein relate generally to switch fabrics and more particularly, to sending data through switch fabrics (e.g., Clos networks).

Known switch fabrics can be multi-stage networks that provide connections between multiple input ports and multiple output ports. Thus, through a switch fabric, a first peripheral device operatively coupled to the switch fabric can send data to a second peripheral device operatively coupled to the switch fabric.

A three-stage Clos network, for example, has a middle stage connected between an input stage and an output stage. Each stage includes multiple modules. Each input stage module has multiple input ports and is operatively coupled to each middle stage module. Similarly, each output stage module has multiple output ports and is connected to each middle stage module.

As the data traverses the switch fabric, each stage determines to which subsequent stage to send the data. To make these decisions, a header (e.g., a packet header) can be used. Each stage of known Ethernet switch fabrics, for example, perform layer 2/layer 3 (L2/L3) packet forwarding, lookup and classification. In some known switch fabrics including more than a single stage, such forwarding, lookup and classification functions can significantly increase the end-to-end latency of the switch fabric. Further, adding additional peripheral devices and/or stages to the switch fabric can significantly increase the end-to-end latency of the switch fabric.

Additionally, known Ethernet switch fabrics often do not ensure that data packets sent from a first peripheral device to a second peripheral device traverse the switch fabric using the same path. Accordingly, packet order is not preserved at the output of the switch fabric and the second peripheral device reorders the data packets, causing further latency and increasing buffering requirements.

Thus, a need exists for a switch fabric that has a relatively low end-to-end latency when compared with known switch fabrics. Additionally, a need exists for a switch fabric that preserves packet ordering.

SUMMARY

A method of sending data to a switch fabric includes assigning a destination port of an output module to a data packet based on at least one field in a first header of the data packet. A module associated with a first stage of the switch fabric is selected based on at least one field in the first header. A second header is appended to the data packet. The second header includes an identifier associated with the destination port of the output module. The data packet is sent to the module associated with the first stage. The module associated with the first stage is configured to send the data packet to a module associated with a second stage of the switch fabric based on the second header.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a schematic illustration of a switch fabric system, according to an embodiment.

FIG. **2** is schematic illustration of a switch fabric system, according to another embodiment.

FIG. **3** is a schematic illustration of a chassis within a switch fabric system, according to another embodiment.

FIGS. **4** and **5** are schematic illustrations of data packets, according to another embodiment.

FIG. **6** is a schematic illustration of a switch fabric system, according to another embodiment.

FIG. **7** is flow chart illustrating a method of sending a data packet through a switch fabric, according to another embodiment.

DETAILED DESCRIPTION

In some embodiments, a method of sending data to a switch fabric includes assigning a destination port of an output module (e.g., an edge device) to a data packet (or a data cell) based on at least one field in a first header of the data packet (or data cell). A module associated with a first stage of the switch fabric is selected based on at least one field in the first header. A second header is appended to the data packet (or data cell). The second header includes an identifier associated with the destination port of the output module. The data packet (or data cell) is sent to the module associated with the first stage. The module associated with the first stage is configured to send the data packet (or data cell) to a module associated with a second stage of the switch fabric based on the second header.

In some embodiments, the first header includes a destination Media Access Control (MAC) address, a destination internet protocol (IP) address, a source MAC address, a source IP address and/or a transfer protocol. A portion of the data in the first header can be used as an input to a hash function. The output of the hash function can identify which module associated with the first stage is selected.

In some embodiments, the second header includes a destination identifier, such as, for example, an identifier of a destination edge device, an identifier of a destination port on a destination edge device, and/or the like. Before entering the switch fabric, the destination identifier can be determined using the data in the first header and a lookup table, which can associate the destination MAC address and/or the destination IP address of a destination peripheral device with a destination port to which the destination peripheral device is coupled.

After the second header is appended to the data packet and the data packet is sent into the switch fabric, the modules associated with the switch fabric can use the destination identifier as an input to a hash function to determine to which module associated with the next stage of the switch fabric to send the data packet. Accordingly, the modules within the switch fabric need not use a lookup table to associate the destination MAC address and/or the destination IP address of the destination peripheral device with the destination port to which the destination peripheral device is coupled because the second header contains the result of such an association. Accordingly, the modules within the switch fabric take less time to route the data packet using the second header, than switch fabrics where the first header alone is used for routing within the switch fabric.

Additionally, in some embodiments, using the destination identifier to route the data packet through the switch fabric ensures that data packets sent from a same source peripheral device to the same destination peripheral device at different times will traverse the switch fabric using the same path as long the switch fabric system is operating in the same configuration at the different times (e.g., the hash functions used are the same, the peripheral devices are coupled to the switch

fabric in the same manner, etc.). In such embodiments, this ensures that the order that the data packets are received by the destination peripheral device is the same as the order in which the data packets were sent by the source peripheral device.

In some embodiments, a switch fabric system includes multiple edge devices, multiple modules associated with a first stage of the switch fabric system, and multiple modules associated with a second stage of the switch fabric system. A first edge device from the set of edge devices is configured to receive a set of data packets. Each data packet from the set of data packets can include a first header. The first edge device is configured to append a second header to each data packet based on at least one field in the first header. The second header includes an identifier associated with a destination port of a second edge device from the set of edge devices. The first edge device is configured to send each data packet from the set of data packets to a module from the plurality of modules associated with the first stage based on the first header. The set of modules associated with the first stage of the switch fabric system is configured to send each data packet from the set of data packets to a module from the set of modules associated with the second stage based on the second header.

In some embodiments, a processor-readable medium stores code representing instructions configured to cause a processor to assign a destination port of an output module (e.g., an edge device) to a data packet based on an identifier of a destination node operatively coupled to the destination port of the output module through at least a switch fabric. The identifier of the destination node is within a first header of the data packet. A second header is appended to the data packet. The second header includes an identifier associated with the destination port of the output module. A module associated with a first stage of the switch fabric is selected using a result of a first hash function having as inputs a set of fields in the first header. The data packet is sent to the module associated with the first stage. The module associated with the first stage is configured to select a module associated with a second stage of the switch fabric using a result of a second hash function having as an input the identifier associated with the destination port of the output module from the second header.

As used herein, a switch fabric system can be a system that includes a switch fabric and devices coupled to the switch fabric. In some embodiments, for example, a switch fabric system can include multiple input/output modules (e.g., an edge device, an access switch, etc.) operatively coupled to the switch fabric such that the input/output modules can send data to and receive data from the switch fabric. Additionally, in some embodiments, the switch fabric system can include peripheral devices (e.g., servers, storage devices, gateways, workstations, etc.) operatively coupled to the input/output modules such that the peripheral devices can send data to and receive data from the switch fabric via the input/output modules. In such embodiments, for example, a first peripheral device can send data to a second peripheral device via the input/output modules and the switch fabric, as described in further detail herein.

As used herein, a switch fabric can be a network that includes multiple stages of switches that operatively connect one or more input devices (e.g., a first edge device) with one or more output devices (e.g., a second edge device). A switch fabric can be configured to receive a signal from an input device, forward the signal through the multiple stages of switches, and output the signal to an output device. Each switch of the multiple stages of switches routes the signal such that the signal arrives at its destination. Such a switch fabric can be referred to, for example, as a Clos network.

As used herein, a module that is within a switch fabric can be any assembly and/or set of operatively coupled electrical components that defines one or more switches within a stage of a switch fabric. An input/output module (e.g., an edge device, an access switch, etc.), for example, can be any assembly and/or set of operatively coupled electrical components configured to send data to and/or receive data from a switch fabric. In some embodiments, for example, an input/output module can be an access switch or an edge device configured receive data from a server, prepare data to enter into the switch fabric, and send the data to the switch fabric. In some embodiments, a module can include, for example, a memory, a processor, electrical traces, optical connectors, and/or the like.

As used in this specification, the singular forms "a," "an" and "the" include plural referents unless the context clearly dictates otherwise. Thus, for example, the term "a module" is intended to mean a single module or a combination of modules.

The terms "first stage", "second stage" and so on refer to portions, modules or nodes within a switch fabric. In some instances, these terms refer to a specific stage within a given switch fabric. For example, a three-stage Clos network includes three consecutive stages from ingress to egress; such a switch fabric has three stages that can be referred to as the "first stage" (the first stage with respect to the ingress to egress direction) through the "third stage" (the third and final stage with respect to the ingress to egress direction). For example, FIGS. **1-7** refer to specific stages within a given switch fabric. In other instances, however, the terms "first stage", "second stage" and so on refer to any stage within the stage fabric and correspond to the order of discussion of a given stage. For example, the "first stage" can refer to the first stage discussed and can correspond to any stage within the switch fabric (e.g., the third stage within a three-stage Clos network), and the "second stage" can refer to a remaining stage within the switch fabric (e.g., the second stage within the three-stage Clos network). Thus, it should be understood that the specific context will indicate whether the terms "first stage", "second stage" and so on can refer to a specific ordinal stage within a switch fabric or can refer to any particular stage within the switch fabric.

FIG. **1** is a schematic illustration of a switch fabric **100**, according to an embodiment. Switch fabric **100** is a three-stage, non-blocking Clos network and includes a first stage **140**, a second stage **142**, and a third stage **144**. The first stage **140** includes modules **112**. Each module **112** of the first stage **140** is an assembly of electronic components and circuitry. In some embodiments, for example, each module is an application-specific integrated circuit (ASIC). In other embodiments, multiple modules are contained on a single ASIC or a single chip package. In still other embodiments, each module is an assembly of discrete electrical components.

In some embodiments, each module **112** of the first stage **140** is a switch (e.g., a packet switch, a frame switch and/or a cell switch). The switches are configured to redirect data (e.g., data packets, data cells, etc.) as it flows through the switch fabric **100**. In some embodiments, for example, each switch includes multiple input ports operatively coupled to write interfaces on a memory buffer (not shown in FIG. **1**). Similarly, a set of output ports are operatively coupled to read interfaces on the memory buffer. In some embodiments, the memory buffer can be a shared memory buffer implemented using on-chip static random access memory (SRAM) to provide sufficient bandwidth for all input ports to write one incoming cell (e.g., a portion of a data packet) or data packet per time period (e.g., one or more clock cycles) and all output

ports to read one outgoing cell or data packet per time period. Each switch operates similar to a crossbar switch that can be reconfigured subsequent each time period.

In alternate embodiments, each module of the first stage is a crossbar switch having input bars and output bars. Multiple switches within the crossbar switch connect each input bar with each output bar. When a switch within the crossbar switch is in an "on" position, the input is operatively coupled to the output and data can flow. Alternatively, when a switch within the crossbar switch is in an "off" position, the input is not operatively coupled to the output and data cannot flow. Thus, the switches within the crossbar switch control which input bars are operatively coupled to which output bars.

Each module **112** of the first stage **140** includes a set of input ports **160** configured to receive data (e.g., a signal, a cell of a packet, a data packet, etc.) as it enters the switch fabric **100**. In this embodiment, each module **112** of the first stage **140** includes the same number of input ports **160**.

Similar to the first stage **140**, the second stage **142** of the switch fabric **100** includes modules **114**. The modules **114** of the second stage **142** are structurally similar to the modules **112** of the first stage **140**. Each module **114** of the second stage **142** is operatively coupled to each module **112** of the first stage **140** by a data path **120**. Each data path **120** between a given module **112** of the first stage **140** and a given module **114** of the second stage **142** is configured to facilitate data transfer from the modules **112** of the first stage **140** to the modules **114** of the second stage **142**.

The data paths **120** between the modules **112** of the first stage **140** and the modules **114** of the second stage **142** can be constructed in any manner configured to facilitate data transfer from the modules **112** of the first stage **140** to the modules **114** of the second stage **142**. In some embodiments, for example, the data paths **120** are optical connectors between the modules. In other embodiments, the data paths are within a midplane. Such a midplane can be similar to that described in U.S. application Ser. No. 12/345,500, filed Dec. 29, 2008, and entitled "System Architecture for a Scalable and Distributed Multi-Stage Switch Fabric," which is incorporated herein by reference in its entirety. Such a midplane can be used to connect each module of the second stage with each module of the first stage. In still other embodiments, two or more modules are contained within a single chip package and the data paths are electrical traces.

In some embodiments, the switch fabric **100** is a non-blocking Clos network. Thus, the number of modules **114** of the second stage **142** of the switch fabric **100** varies based on the number of input ports **160** of each module **112** of the first stage **140**. In a rearrangeably non-blocking Clos network (e.g., a Benes network), the number of modules **114** of the second stage **142** is greater than or equal to the number of input ports **160** of each module **112** of the first stage **140**. Thus, if n is the number of input ports **160** of each module **112** of the first stage **140** and m is the number of modules **114** of the second stage **142**, m≥n. In some embodiments, for example, each module of the first stage has five input ports. Thus, the second stage has at least five modules. All five modules of the first stage are operatively coupled to all five modules of the second stage by data paths. Said another way, each module of the first stage can send data to any module of the second stage.

The third stage **144** of the switch fabric **100** includes modules **116**. The modules **116** of the third stage **144** are structurally similar to the modules **112** of the first stage **140**. The number of modules **116** of the third stage **144** is typically equivalent to the number of modules **112** of the first stage **140**. Each module **116** of the third stage **144** includes output ports **162** configured to allow data to exit the switch fabric **100**. Each module **116** of the third stage **144** includes the same number of output ports **162**. Further, the number of output ports **162** of each module **116** of the third stage **144** is typically equivalent to the number of input ports **160** of each module **112** of the first stage **140**.

Each module **116** of the third stage **144** is connected to each module **114** of the second stage **142** by a data path **124**. The data paths **124** between the modules **114** of the second stage **142** and the modules **116** of the third stage **144** are configured to facilitate data transfer from the modules **114** of the second stage **142** to the modules **116** of the third stage **144**.

The data paths **124** between the modules **114** of the second stage **142** and the modules **116** of the third stage **144** can be constructed in any manner configured to facilitate data transfer from the modules **114** of the second stage **142** to the modules **116** of the third stage **144**. In some embodiments, for example, the data paths **124** are optical connectors between the modules. In other embodiments, the data paths are within a midplane. Such a midplane can be similar to that described in further detail herein. Such a midplane can be used to connect each module of the second stage with each module of the third stage. In still other embodiments, two or more modules are contained within a single chip package and the data paths are electrical traces.

FIG. **2** is schematic illustration of a switch fabric system **200**, according to another embodiment. The switch fabric system **200** includes a switch fabric **230**, multiple edge devices **250** operatively coupled to the switch fabric **230**, and multiple peripheral devices **270** operatively coupled to the edge devices **250**. As described in further detail herein and as shown by path **222** in FIG. **2**, a first peripheral device **270** (e.g., S_1) is configured to send a data packet to a second peripheral device **270** (e.g., S_6) via a first edge device **250** (e.g., E_1), the switch fabric **230**, and a second edge device **250** (e.g., E_3).

The switch fabric **230** can be structurally and functionally similar to the switch fabric **100**. Accordingly, the switch fabric includes modules F_1-F_N associated with a first stage **232** of the switch fabric **230**, modules G_1-G_N associated with a second stage **234** of the switch fabric **230**, and modules H_1-H_N associated with a third stage **236** of the switch fabric. Each module F_1-F_N associated with the first stage **232** is operatively coupled to each module G_1-G_N associated with the second stage **234** via data paths. Similarly, each module G_1-G_N associated with the second stage **234** is operatively coupled to each module H_1-H_N associated with the third stage **236**. The data paths between the modules F_1-F_N associated with the first stage **232** and the modules G_1-G_N associated with the second stage **234** and/or the data paths between the modules G_1-G_N associated with the second stage **234** and the modules H_1-H_N associated with the third stage **236** can be constructed in any manner configured to facilitate data transfer. In some embodiments, for example, the data paths include optical connectors and optical fibers between the modules. In other embodiments, the data paths are within a midplane.

The modules F_1-F_N associated with a first stage **232** are configured to send data (e.g., data packets, data cells, etc.) to modules G_1-G_N associated with a second stage **234**. As described in further detail herein, in some embodiments, a module F_1-F_N associated with the first stage **232** is configured to determine to which module G_1-G_N associated with the second stage **234** to send the data packet based on a header of the data packet (e.g., destination identifier **432** shown and described with respect to FIG. **5**). The module F_1-F_N associated with the first stage **232** can, for example, select the module G_1-G_N associated with the second stage **234** based on

a result of a hash function using as an input the contents of the header (e.g., destination identifier **432** shown and described with respect to FIG. **5**), as described in further detail herein. In some embodiments, for example, the hash function can use shift registers similar to the hash functions shown and described in U.S. patent application Ser. No. 12/242,158, filed on Sep. 30, 2008, and entitled "Methods and Apparatus for Producing a Hash Value based on a Hash Function," which is incorporated herein by reference in its entirety.

The peripheral devices **270** can be, for example, servers, storage devices, gateways, workstations, and/or the like. The peripheral devices **270** can be operatively coupled to the edge devices **250** using any suitable connection. For example, FIG. **3** illustrates a chassis **350** including an edge device **355** and multiple peripheral devices **360** operatively coupled to the edge device **355** via a backplane (not shown in FIG. **3**). As such, the peripheral devices **360** are configured to send data (e.g., data packets, data cells, etc.) to the edge device **355** via the backplane. While shown in FIG. **3** as being disposed within a same chassis **350** as an edge device **355**, in other embodiments, the peripheral devices are disposed remote from the edge device and are operatively coupled to the edge device via an optical connection (e.g., an optical cable and optical connectors), an electrical connection (e.g., an electrical cable and electrical connectors) and/or the like. Further, while the edge device **355** is shown as being operatively coupled to eight peripheral devices **360**, in other embodiments, the edge device can be coupled to any number of peripheral devices. In some embodiments, for example, each edge device is operatively coupled to 48 peripheral devices.

The edge devices **250** can be any devices configured to operatively couple peripheral devices **270** to the switch fabric **230**. In some embodiments, for example, the edge devices **250** can be access switches, input/output modules, top-of-rack devices and/or the like. Edge devices E_1 and E_2 are schematically shown as source edge devices and edge device E_3 is schematically shown as a destination edge device for illustration purposes only. Structurally, the edge devices **250** (including E_1, E_2, and E_3) can function as source edge devices and destination edge devices. Accordingly, the edge devices **250** can send data to and receive data from the switch fabric **230**.

The edge devices **250** can store Media Access Control (MAC) addresses for other edge devices **250** and/or peripheral devices **270** within the switch fabric system **200**. For example, an edge device E_3 can store the MAC addresses of the peripheral devices S_5, S_6 coupled to the edge device E_3. Using the MAC addresses of the peripheral devices S_5, S_6, the edge device E_3 can properly forward data packets to its destination when a data packet is received. In some embodiments, for example, an edge device **250** can be coupled to 48 peripheral devices **270** each running multiple virtual machines. If, for example, each peripheral device **270** is running 50 virtual machines, the edge device **250** will store 2400 MAC addresses of edge devices **250** to which it is coupled (e.g., source MAC address (SMACs)). In other embodiments, any number of peripheral devices running any number of virtual machines can be coupled to the edge device.

In some embodiments, the edge devices **250** also store multiple destination MAC addresses (DMACs). Such DMACs can be associated with peripheral devices **270** to which the peripheral devices **270** coupled to an edge device **250** can send data. For example, an edge device E_1 can store the MAC addresses of the peripheral devices S_5, S_6 and associate the MAC addresses with a destination port of E_3. Accordingly, the MAC address of peripheral device S_5 is associated with destination port **252** and the MAC address of S_6 is associated with destination port **253**. In some embodiments, an edge device **250** can be coupled to 48 peripheral devices **250** each running 2400 virtual machines. If, for example, each of the 2400 virtual machines is sending data to or receiving data from a connection with 25 other virtual machines coupled to another edge device **250**, the edge device **250** can store 60000 DMACs. In such an embodiment, each edge device **250** can store a total of 62400 MAC addresses (e.g., 60000 DMACs+2400 SMACs). In other embodiments, each edge device **250** can store any number of DMACs and/or SMACs.

In some embodiments, each edge device **250** includes a lookup table that associates the MAC addresses (e.g., the DMACs and the SMACs) with the port of an edge device **250** to which the peripheral device having the MAC address is coupled. For example, such a lookup table can associate S_5 with port **252** and S_6 with **253**. In such embodiments, the edge device **250** can use the lookup table to determine how to forward the data packet, as described in further detail herein.

The edge devices **250** can be configured to prepare a data packet to enter the switch fabric **230**. For example, the edge device **250** can be configured to forward, classify, and/or modify the packet encapsulation of a data packet prior to sending the data packet to the switch fabric **230**. As described in further detail herein, in some embodiments, for example, a hash function using data stored within a header of a data packet (e.g., header portion **423** of FIG. **4**) as an input is used to determine to which module F_1-F_N associated with a first stage **232** the edge device **250** should send the data packet. In some embodiments, for example, the hash function can use shift registers similar to the hash functions shown and described in U.S. patent application Ser. No. 12/242,158, referenced above.

Additionally, as described in further detail herein, data within the header of a data packet (e.g., header portion **423** of FIG. **4**) can be used to identify a destination port of a destination edge device **250** (e.g., destination port **252** or **253**). An identifier of the destination port of the destination edge device **250** can be appended to the data packet (e.g., destination identifier **422** of FIG. **5**). The identifier of the destination port can be used by the modules F_1-F_N, G_1-G_N, H_1-H_N within the switch fabric **230** to correctly send the data packet through the switch fabric **230**, as described in further detail herein.

In use, for example, a peripheral device S_1 can be configured to send a data packet to another peripheral device S_6, via path **222** (e.g., via an edge device E_1, the switch fabric **230** and an edge device E_3). FIG. **2** represents the peripheral device S_1 sending a data packet to peripheral device S_6 by way of example. Any peripheral device **270** operatively coupled to the switch fabric **230** via an edge device **250** can be configured to send a data packet to any other peripheral device **270** coupled to the switch fabric **230** via an edge device **250**.

The peripheral device S_1 can send the data packet to the edge device E_1. The data packet can be similar to the data packet **420** shown and described in FIG. **4**. The data packet **420** includes a packet data portion **425** and a packet header portion **423**. The packet data portion **425** includes the information to be sent to peripheral device S_6. The packet header portion **423** includes identifying information. In some embodiments, for example, the packet header portion **423** can include at least a portion of an IP 5-tuple. In such embodiments, for example, the packet header portion **423** can include a destination MAC address, a destination internet protocol (IP) address, a source MAC address, a source IP address and/or a transfer protocol. In the present example, the destination MAC address and the destination IP address can be

associated with peripheral device S_6 and the source MAC address and the source IP address can be associated with peripheral device S_1.

The edge device E_1 receives the data packet **420** and parses the packet header portion **423** of the data packet **420**. In some embodiments, the edge device E_1 can use the destination MAC address in the packet header portion in conjunction with a lookup table stored at the edge device E_1 to determine an identifier of the destination port (e.g., port **253**) to which the peripheral device S_6 is coupled and/or an identifier of a destination edge device E_3 to which the peripheral device S_6 is coupled. The lookup table can, for example, correlate the destination MAC address with the identifier of the destination port (e.g., port **253**) and/or the identifier of the destination edge device E_3. In some embodiments, for example, the identifier can be a port number, an address (e.g., MAC address, IP address, etc.), an internal unique identifier, an identifier of the second peripheral device itself, and/or any other suitable identifier used to identify the destination peripheral device's S_6 position within the switch fabric system **200**.

A destination identifier portion (e.g., a second header) containing an identifier associated with the destination port (e.g., port **253**) and/or an identifier associated with a destination edge device E_3 can be appended to the data packet **420**. For example, FIG. **5** illustrates a data packet **430** having a packet data portion **435**, a packet header portion **433** (e.g., a first header), and a destination identifier portion **432** (e.g., a second header). In other embodiments, any other identifier associated with the destination edge device E_3, the destination port of the edge device E_3, and/or the destination peripheral device S_6 can be appended to the data packet as a destination identifier portion.

Using the information contained within the packet header portion **433** of the data packet **430**, the edge device E_1 can determine to which module F_1-F_N to send the data packet **430**. While shown in FIG. **2** as being operatively coupled to a single module F_1 associated with the first stage, the edge device E_1 can be coupled to any number of modules associated with the first stage. Additionally, while shown in FIG. **2** as being operatively coupled to a single switch fabric **230**, the edge device E_1 can be operatively coupled to any number of switch fabrics, similar to switch fabric **230**. In some embodiments, for example, the edge device E_1 can be both coupled to the module F_1 associated with the first stage of the switch fabric **230** and a module associated with a first stage of a second switch fabric (not shown in FIG. **2**). In such embodiments, the edge device E_1 can send data to either the module F_1 or the module associated with the first stage of the second switch fabric.

In some embodiments, for example, the edge device E_1 can use a hash function using as inputs the destination MAC address, the destination IP address, the source MAC address, the source IP address, and/or the transfer protocol. Based on the inputs, the hash function can generate an identifier associated with a module (e.g., module F_1) associated with the first stage **232** of the switch fabric **230**. In some embodiments, the identifier generated by the hash function can be associated with the module F_1 using a lookup table to determine to which output port of the edge device E_1 the module F_1 is coupled and/or the like. In other embodiments, the identifier produced from the hash function can be an identifier of an output port of the edge device E_1 to which the module F_1 is coupled. In still other embodiments, any other method of associating the identifier generated by the hash function with the module F_1 can be used. Because the identifier associated with the module F_1 is generated based on the information in the packet header portion **433** of the data packet **430**, every data packet sent from peripheral S_1 to peripheral S_6 will be sent to the same module (e.g., module F_1) associated with the first stage **232**.

After the module F_1 associated with the first stage **232** receives the data packet **430**, it parses the destination identifier portion **432** of the data packet **430**. Using the destination identifier within the destination identifier portion **432**, the module F_1 can determine to which module G_2 associated with the second stage **234** of the switch fabric **230** to send the data packet **430**. In some embodiments, for example, the module F_1 can use a hash function using as an input the destination identifier **432**. Based on the destination identifier **432**, the hash function can generate an identifier associated with a module (e.g., module G_2) associated with the second stage **234**, and send the data packet **430** accordingly. In some embodiments, the identifier generated by the hash function can be associated with the module G_1 using a lookup table to determine to which output port of the module F_1 the module G_1 is coupled and/or the like. In other embodiments, the identifier produced from the hash function can be an identifier of an output port of the module F_1 to which the module G_1 is coupled. In still other embodiments, any other method of associating the identifier generated by the hash function with the module G_1 can be used. Because the result of the hash function is based on the destination identifier **432**, all data packets **430** within the module F_1 being sent to the peripheral device S_6 will be sent by F_1 to the same module G_2 associated with the second stage **234**.

The amount of time the module F_1 takes to determine to which module to send the data packet **430** can be decreased by using a destination identifier portion **432** of the data packet **430** instead of the packet header portion **433**. In some embodiments, for example, the destination identifier portion **433** can be smaller (e.g., fewer bytes of memory) and contain fewer fields than the packet header portion **433**. Thus, parsing the destination identifier portion **432** can be faster than parsing the packet header portion **433**. Additionally, using a hash function allows the module F_1 to quickly determine to which module to send the data packet **430**. Such a hash function can be easily implemented and allows for a quick identification of the appropriate module based on the destination identifier portion **432**.

Additionally, because a destination MAC address is associated with a destination identifier (e.g., a destination port, a destination edge device E_3, etc.) at the edge device E_1, the module F_1 can forward the data packet **430** without associating a destination MAC address with a destination identifier. This reduces the amount of time used by the module F_1 when determining to which module G_1-G_N to send the data packet **430**. This also reduces the amount of memory used by the module F_1 because the module F_1 need not store associations between a destination MAC address and destination identifiers. Further, because the association of a destination MAC address with a destination identifier is performed at the edge device E_1 and the result stored in the destination identifier portion **432**, the modules within the switch fabric **230** need not perform such an association. Moreover, the module F_1 can forward the data packet **430** without performing standard layer 2/layer 3 (L2/L3) forwarding, lookup and classification functions (commonly used in Ethernet switch fabrics).

After the module G_2 associated with the second stage **234** receives the data packet **430**, it parses the destination identifier portion **432** of the data packet **430**, similar to the module F_1. Using the destination identifier within the destination identifier portion **432**, the module G_2 can determine to which module H_1-H_N associated with the third stage **236** of the switch fabric **230** to send the data packet **430**. In some embodiments, for example, the module G_2 can use a hash

function using as an input the destination identifier. Based on the destination identifier, the hash function can generate an identifier associated with a module (e.g., module H_2) associated with the third stage **236**, and send the data packet **430** accordingly. Because the result of the hash function is based on the destination identifier, all data packets **430** within the module G_2 being sent to the peripheral device S_6 will be sent by G_2 to the same module H_2 associated with the second stage **234**.

Similarly, after the module H_2 associated with the third stage **236** receives the data packet **430**, it parses the destination identifier portion **432** of the data packet **430**, similar to the module F_1. Using the destination identifier within the destination identifier portion **432**, the module H_2 can determine to which edge device E_3 to send the data packet **430**. In some embodiments, for example, the module H_2 can use a hash function using as an input the destination identifier. Based on the destination identifier, the hash function can generate an identifier associated with an edge device E_3, and send the data packet **430** accordingly. Because the result of the hash function is based on the destination identifier, all data packets **430** within the module H_2 being sent to the peripheral device S_6 will be sent by H_2 to the same edge device E_3.

After the edge device E_3 receives the data packet **430**, the edge device **430** can determine to which peripheral device S_6 to send the data packet **430** and send the data packet **430** accordingly. In some embodiments, the edge device E_3 can parse the destination identifier portion **432** of the data packet **430**. If the destination identifier portion **432** includes an identifier of a specific port **253**, the edge device E_3 can send the data packet to the peripheral device S_6 operatively coupled to the port **253**. In other embodiments, the edge device E_3 can parse the packet header portion **433**. Using the stored SMACs and the destination MAC address in the packet header portion **433**, the edge device E_3 can determine to which port **253** the destination peripheral device S_6 is coupled and send the data packet accordingly. In some embodiments, prior to sending the data packet **430** to the destination peripheral device S_6, the destination identifier portion **432** is removed from the data packet **430**. Accordingly, in such embodiments, the destination peripheral device S_6 receives a data packet similar to the data packet **420** of FIG. **4**.

As discussed above, because the routing decision at the edge device E_1 is based on a hash function using as inputs a destination MAC address, a destination IP address, a source MAC address, a source IP address and/or a transfer protocol (e.g., the data within a packet header portion of a data packet), each data packet sent from a first peripheral device (e.g., S_1) to a second peripheral device (e.g., S_6) is sent to the same module F_1 associated with the first stage **232**. Additionally, as discussed above, because the routing decisions in the switch fabric **230** (e.g., at modules F_1, G_2, and H_2) are based on the a destination identifier portion **432** appended to the data packet **430** at the edge device E_1, each data packet **430** sent from the first peripheral device (e.g., S_1) to the second peripheral device (e.g., S_6) traverses the same path **222** through the switch fabric **230** (e.g., from F_1 to G_2, from G_2 to H_2, and from H_2 to E_3). This ensures that each data packet sent from the first peripheral device (e.g., S_1) to the second peripheral device (e.g., S_6) traverses the switch fabric system **200** using the same path **222**. Accordingly, the order in which packets are sent from the first peripheral device (e.g., S_1) to the second peripheral device (e.g., S_6) is preserved. Said another way, if a second data packet is sent from peripheral device S_1 to peripheral device S_6 after a first data packet is sent from peripheral device S_1 to peripheral device S_6, the first data packet will arrive at peripheral device S_6 prior to the second data packet arriving at peripheral device S_6.

FIG. **6** is a schematic illustration of a switch fabric system **500**, according to another embodiment. The switch fabric system **500** includes multiple edge devices **550** and a switch fabric chassis **530**. The multiple edge devices **550** can be similar to the edge devices **250** shown and described above with respect to FIG. **2**. As such, each edge device **550** can be operatively coupled to multiple peripheral devices (not shown in FIG. **6**) and to the switch fabric chassis **530**. The peripheral devices can be similar to the peripheral devices **270** shown and described above with respect to FIG. **2**. As such, the peripheral devices **270** can send data (e.g., data packets, data cells, etc.) to and receive data (e.g., data packets, data cells, etc.) from the edge devices **550**.

The edge devices **550** include multiple cable connector ports **582** each configured to be coupled to an end portion of a cable **580**. Through the cables **580**, each edge device **550** can be operatively coupled to the switch fabric chassis **530**. Each edge device **550** can function as a source edge device and a destination edge device. Accordingly, each edge device **550** can send data to and receive data from the switch fabric chassis **530**.

The cables **580** can be constructed of any material suitable to transfer data between the edge devices **550** and the switch fabric chassis **530**. In some embodiments, for example, each cable **580** is constructed of multiple optical fibers. In such an embodiment, each cable **580** can have, for example, twelve transmit and twelve receive fibers. The twelve transmit fibers of each cable **580** can include eight fibers for transmitting data, one fiber for transmitting a control signal, and three fibers for expanding the data capacity and/or for redundancy. Similarly, the twelve receive fibers of each cable **580** have eight fibers for receiving data, one fiber for receiving a control signal, and three fibers for expanding the data capacity and/or for redundancy. In other embodiments, any number of fibers can be contained within each cable. In some embodiments, for example, the cables **580** can be 40 gigabit (40G) cables. The transmit and receive designations of the fibers are from the perspective of the edge devices **550**. The designations are opposite if viewed from the perspective of the switch fabric chassis **530**.

While shown in FIG. **6** as being operatively coupled to a single switch fabric chassis **530**, in some embodiments, each edge device **550** is operatively coupled to a second switch fabric chassis (not shown in FIG. **6**). In such embodiments, for example, the cables **581** (which can be structurally and functionally similar to cables **580**) can be used to operatively couple the edge devices **550** to a second switch fabric chassis. In other embodiments, each edge device can be operatively coupled to any number of switch fabric chassis using any number of cables.

The switch fabric chassis **530** includes multiple interface cards **560** (only a single interface card **560** from a set of multiple interface cards **560** is shown in FIG. **6**), multiple interface cards **570** (only a single interface card **570** from a set of multiple interface cards **570** is shown in FIG. **6**) and a midplane **590**. In some embodiments, the midplane **590** can be configured to operatively couple each interface card **560** with each interface card **570**. Accordingly, a 1st/3rd stage module system **562** on an interface card **560** can send data to and/or receive data from any 2nd stage module system **572** on any of the interface cards **570**. Similarly, a 2nd stage module system **572** on an interface card **570** can send data to and/or receive data from any 1st/3rd stage module system **562** on any of the interface cards **560**. In some embodiments, the midplane **590** can include multiple 20 gigabit (20G) connections

between the interface cards **560** and the interface cards **570**. As discussed above, in some embodiments, the midplane **590** can be similar to the midplane shown and described in U.S. application Ser. No. 12/345,500, filed Dec. 29, 2008, and entitled "System Architecture for a Scalable and Distributed Multi-Stage Switch Fabric," which is incorporated herein by reference in its entirety.

The interface card **560** includes multiple cable connector ports **584** and multiple 1st/3rd stage module systems **562**. The cable connector ports **584** can be similar to the cable connector ports **582**. Accordingly, each cable connector port **584** can be configured to receive an end of a cable **580**. Via a cable connector port **582**, a cable **580** and a cable connector port **584**, an edge device **550** can be operatively coupled to an interface card **560**.

Each 1st/3rd stage module system includes a module associated with a first stage of the switch fabric system **500** and a module associated with a third stage of the switch fabric system **500**. The module associated with the first stage and the module associated with the third stage can be similar to the modules **232** and the modules **234**, respectively, shown and described above with respect to FIG. **2**.

The 1st/3rd stage module systems **562** can be application-specific integrated circuits (ASICs) or chip packages having multiple ASICs. The 1st/3rd stage module systems **562** can be instances of the same ASIC or chip package. Said another way, the ASIC or chip package of each 1st/3rd stage module system **562** can be substantially similar (i.e., the same kind or type) to the ASIC or chip package of other 1st/3rd stage module systems **562**. Thus, manufacturing costs can be decreased because multiple instances of a single ASIC or chip package can be produced.

The interface card **570** includes multiple 2nd stage module systems **572**. Each 2nd stage module system **572** includes a module associated with a second stage of the switch fabric system **500**. The module associated with the second stage can be similar to the modules **236**, respectively, shown and described above with respect to FIG. **2**.

Similar to the 1st/3rd stage module systems **562**, the 2nd stage module systems **572** can be application-specific integrated circuits (ASICs) or chip packages having multiple ASICs. The 2nd stage module systems **572** can be instances of the same ASIC or chip package. Said another way, the ASIC or chip package of each 2nd stage module system **572** can be substantially similar (i.e., the same kind or type) to the ASIC or chip package of other 2nd stage module systems **562**. Thus, manufacturing costs can be decreased because multiple instances of a single ASIC or chip package can be produced.

In some embodiments, the switch fabric system **500** includes eight interface cards **560** each operatively coupled to eight interface cards **570** through the midplane **590**. In such embodiments, each interface card **560** can include sixteen cable connector ports **584**. As such, the switch fabric chassis **530** can include 128 cable connector ports **584** to which edge devices **550** can be coupled (8 interface cards (**560**)×16 cable connector ports (**584**) per interface card (**560**)=128 total cable connector ports **584**). Accordingly, in such embodiments, 128 edge devices **550** can be coupled to the switch fabric chassis **530**.

In use, the switch fabric system **500** functions similar to the switch fabric system **200**, shown and described above. As such a first peripheral device (not shown in FIG. **6**) coupled to a first edge device **550** can be configured to send a data packet to a second peripheral device (not shown in FIG. **6**) coupled to a second edge device **550**, via the first edge device **550**, the switch fabric chassis **530** and the second edge device **550**.

The first peripheral device can send the data packet to the first edge device **550**. The data packet can be similar to the data packet **420** shown and described in FIG. **4**, and can include a packet data portion **425** and a packet header portion **423**. The packet data portion **425** includes the information to be sent to second peripheral device. The packet header portion **423** includes identifying information. As discussed above, in some embodiments, for example, the packet header portion **423** can include at least a portion of the IP 5-tuple. In such embodiments, for example, the packet header portion can include a destination MAC address, a destination IP address, a source MAC address, a source IP address and/or a transfer protocol. In the present example, the destination MAC address and the destination IP address can be associated with the second peripheral device; the source MAC address and the source IP address can be associated with the first peripheral device.

The edge device **550** receives the data packet and parses the packet header portion of the data packet. In some embodiments, for example, the edge device **550** can use the destination MAC address in the packet header portion in conjunction with a lookup table stored at the edge device **550** to determine an identifier of the destination port to which the second peripheral device is coupled and/or an identifier of a destination edge device **550** to which the second peripheral device is coupled. The lookup table can, for example, correlate the destination MAC address with the identifier of the destination port and/or the identifier of the destination edge device **550**. In some embodiments, for example, the identifier can be a port number, an address (e.g., MAC address, IP address, etc.), an internal unique identifier, an identifier of the second peripheral device itself, and/or any other suitable identifier used to identify the destination peripheral device's position within the switch fabric system **500**.

A destination identifier portion (e.g., a second header) containing the identifier associated with the destination port and/or the identifier associated with a destination edge device **550** can be appended to the data packet **420**. For example, FIG. **5** illustrates a data packet **430** having a packet data portion **435**, a packet header portion **433** (e.g., a first header), and a destination identifier portion **432** (e.g., a second header). In other embodiments, any other identifier associated with the destination edge device, the destination port of the edge device, and/or the second peripheral device can be appended to the data packet as a destination identifier portion.

Using the information contained within the packet header portion **433** of the data packet **430**, the edge device **550** can determine to which 1st/3rd stage module system **562** to send the data packet **430**. While shown in FIG. **6** as being operatively coupled to a single 1st/3rd stage module **562**, each edge device **550** can be coupled to any number of 1st/3rd stage module systems **562**. Similarly, each edge device **550** can be operatively coupled to any number of switch fabrics.

In some embodiments, for example, the edge device **550** can use a hash function using as inputs the destination MAC address, the destination IP address, the source MAC address, the source IP address, and/or the transfer protocol. Based on the inputs, the hash function can generate an identifier associated with a first stage module within a 1st/3rd stage module system **562**. Because the identifier associated with the module is generated based on the information in the header portion **433** of the data packet **430**, every data packet sent from the first peripheral device to the second peripheral device will be sent to the same 1st/3rd stage module system **562**.

Additionally, as described above, in some embodiments, each edge device **550** can be coupled to more than one switch fabric. In such embodiments, the hash function at the edge

device can be used by the edge device to determine to which switch fabric to send the data. For example, depending on the result of the hash function, the edge device **550** can send the data via a cable **580** to the first switch fabric chassis **530** or can send the data via a cable **581** to the second switch fabric chassis (not shown in FIG. **6**).

After the module associated with the first stage within the 1st/3rd stage module system **562** receives the data packet **430**, it parses the destination identifier portion **432** of the data packet **430**. Using the destination identifier within the destination identifier portion **432**, the first stage module can determine to which second stage module system **572** to send the data packet **430**. In some embodiments, for example, the first stage module can use a hash function using as an input the destination identifier. Based on the destination identifier, the hash function can generate an identifier associated with a second stage module within a second stage module system **572**, and send the data packet **430** accordingly. Because the result of the hash function is based on the destination identifier, all data packets **430** within the same first stage module being sent to the same peripheral device will be sent by the first stage module to the same second stage module.

The amount of time a first stage module takes to determine to which second stage module to send the data packet **430** can be decreased by using a destination identifier portion **432** of the data packet **430** instead of the packet header portion **433**. In some embodiments, for example, the destination identifier portion **433** can be smaller (e.g., fewer bytes of memory) and contain fewer fields than the packet header portion **433**. Thus, parsing the destination identifier portion **432** can be faster than parsing the packet header portion **433**. Additionally, using a hash function allows a first stage module to quickly determine to which second stage module to send the data packet **430**. Such a hash function can be easily implemented and allows for a quick identification of the appropriate second stage module based on the destination identifier portion **432**.

Additionally, because a destination MAC address is associated with a destination identifier (e.g., a destination port, a destination edge device **550**, etc.) at the source edge device **550**, the first stage module can forward the data packet **430** without associating a destination MAC address with a destination identifier. This reduces the amount of time used by the first stage module when determining to which second stage module to send the data packet **430**. This also reduces the amount of memory used by the first stage module as the first stage module need not store associations between a destination MAC address and destination identifiers (e.g., the first stage module need not store a lookup table). Further, because the association of a destination MAC address with a destination identifier is performed at a source edge device **550** and the result stored in the destination identifier portion **432**, the modules within the switch fabric chassis **530** need not perform such an association. Moreover, the first stage module can forward the data packet **430** without performing standard L2/L3 forwarding, lookup and classification functions (commonly used in Ethernet switch fabrics).

As shown in FIG. **6**, the data is sent from the 1st/3rd stage module system **562** to a 2nd stage module system **572** via the midplane **590**. As discussed above, each interface card **560** can be operatively coupled to eight interface cards **570** via the midplane **590**. As such, based on the destination identifier, the 1st/3rd stage module system **562** can send the data to a 2nd stage module system **572** on any of the eight interface cards **570** via the midplane **590**.

Similar to the first stage module within the 1st/3rd stage module system **562**, the second stage module within the 2nd stage module system **572** can parse the destination identifier portion **432** of the data packet **430** and use the destination identifier portion **432** (e.g., as an input to a hash function) to determine to which third stage module within a 1st/3rd stage module system **562** to send the data packet **430**. The data packet **430** can be sent to the 1st/3rd stage module system **562** via the midplane **590**.

Further, the third stage module within the 1st/3rd stage module system **562** can parse the destination identifier portion **432** of the data packet **430** and use the destination identifier portion **432** (e.g., as an input to a hash function) to determine to which edge device **550** to send the data packet. The data packet **430** can be sent to the edge device **550** via a cable **580**.

As discussed above, because the routing decision at the source edge device **550** is based on a hash function using as inputs a destination MAC address, a destination IP address, a source MAC address, a source IP address and/or a transfer protocol, each data packet sent from a first peripheral device to a second peripheral device is sent to the same first stage module within the same 1st/3rd stage module system **562**. Additionally, as discussed above, because the routing decisions in the switch fabric chassis **530** (e.g., at the 1st/3rd stage module systems **562** and the 2nd stage module systems **572**) are based on the a destination identifier portion **432** appended to the data packet **430** at the source edge device **550**, each data packet **430** sent from the first peripheral device to the second peripheral device traverses the same path through the switch fabric chassis **530** (e.g., passes through the same module systems **562**, **572**). This ensures that each data packet sent from the first peripheral device to the second peripheral device traverses the switch fabric system **500** using the same path. Accordingly, the order in which packets are sent from the first peripheral device to the second peripheral device is preserved. Said another way, if a second data packet is sent from the first peripheral device to the second peripheral device after a first data packet is sent from the first peripheral device to the second peripheral device, the first data packet will arrive at second peripheral device prior to the second data packet arriving at the second peripheral device.

In some embodiments, a control module (not shown in FIG. **6**) can be disposed on each interface card **560**, **570** and/or at each edge device **550**. Such a control module can include a processor and a memory. In such embodiments, the control module can receive control signals from the switch fabric system **500** relating to the operation of the switch fabric system **500**. For example, flow control signals, error signals and/or the like can be sent to the control module. In such embodiments, control of the switch fabric system can be said to be distributed. In other embodiments, the control module can be a central control module operatively coupled to each interface card and/or each edge device. In such embodiments, the central control module controls the module systems and/or the edge devices. In some embodiments, the switch fabric system **500** can be controlled similar to the systems shown and described in U.S. patent application Ser. No. 12/345,498, filed Dec. 29, 2008, and entitled "Control Plane Architecture for Switch Fabrics," which is incorporated herein by reference in its entirety. Further, in some embodiments, a network administrator can view control information regarding the components of the switch fabric system **500** on a single display.

FIG. **7** is flow chart illustrating a method **600** of sending a data packet through a switch fabric, according to another embodiment. The method **600** includes assigning a destination port of an output module to a data packet based on at least one field in a first header of the data packet, at **602**. The output module can be, for example, similar to the edge devices

shown and described above. The destination port of the output module can be coupled to a destination peripheral device.

In some embodiments, the first header can be similar to the packet header portion **423** shown and described with respect to FIG. **4**. As such, the first header can include a destination MAC address, a destination internet protocol (IP) address, a source MAC address, a source IP address and/or a transfer protocol. In other embodiments, the first header can include any other data associated with the switch fabric system and/or the data packet.

A module associated with a first stage of the switch fabric is selected based on at least one field in the first header, at **604**. The module associated with the first stage can be selected using a hash function. The hash function can use as inputs at least one field in the first header. Because the module associated with the first stage is selected based on the fields in the first header, the same module associated with the first stage will be selected for other data packets having a similar first header (e.g., a second data packet's source and destination are the same as the first data packet's source and destination).

A second header is appended to the data packet, at **606**. The second header includes an identifier associated with the destination port of the output module. The second header can be similar to the destination identifier portion **432** shown and described with respect to FIG. **5**. As such, the second header can include a destination identifier, such as, for example, an identifier of a destination edge device, an identifier of a destination port at a destination edge device, and/or the like. The destination identifier can be determined using the data in the first header and a lookup table, which can associate the destination MAC address and/or the destination IP address of a destination peripheral device with a destination port to which the destination peripheral device is coupled.

The data packet is sent to the module associated with the first stage, at **608**. The module associated with the first stage is configured to send the data packet to a module associated with a second stage of the switch fabric based on the second header. In some embodiments, the module associated with the first stage can use the destination identifier as an input to a hash function to determine to which module associated with the next stage of the switch fabric to send the data packet. Accordingly, the module associated with the first stage need not use a lookup table to associate the destination MAC address and/or the destination IP address of the destination peripheral device with the destination port to which the destination peripheral device is coupled because the second header contains the result of such an association.

Additionally, using the destination identifier to route the data packet through the switch fabric ensures that data packets sent from a same source peripheral device to the same destination peripheral device will traverse the switch fabric using the same path. This ensures that the order the data packets are received by the destination peripheral device is the same as the order in which the data packets were sent by the source peripheral device.

While various embodiments have been described above, it should be understood that they have been presented by way of example only, and not limitation. Where methods described above indicate certain events occurring in certain order, the ordering of certain events may be modified. Additionally, certain of the events may be performed concurrently in a parallel process when possible, as well as performed sequentially as described above.

While shown and described above as using hash functions to determine how to route data through a switch fabric, in other embodiments, any other suitable function can be used to route data through the switch fabric. Some embodiments can include, for example, a mapping function such as a lookup table and/or the like used to route data through the switch fabric.

Further, any suitable type of hash function can be used to route data through the switch fabric. Some embodiments can include, for example, cyclic redundancy check hash functions, checksum hash functions, secure hash algorithms (SHA) such as SHA1, SHA256, etc., message digest (MD) algorithms such as MD2, MD4, MD5, etc., Pearson hash functions, Fowler-Noll-Vo hash functions, Bloom filters and/or the like.

While shown and described as having three-stages, the switch fabric systems shown and described herein can be upgraded to switch fabrics having any number of stages greater than three stages without significantly increasing the end-to-end latency of the switch fabric system. For example, the switch fabric system **500** can be upgraded to a five-stage switch fabric system. Because the modules within the switch fabric do not parse the packet header of the data packet (e.g., packet header **433** of data packet **430** shown in FIG. **5**), the modules within the switch fabric can route data through the switch fabric faster than modules that do parse the packet header of the data packet and perform normal L2/L3 forwarding, lookup, and classification functions. Accordingly, when switch fabric system **500** is upgraded, the end-to-end latency is not significantly increased when compared to a switch fabric having modules that parse the packet header of the data packet.

Some embodiments described herein relate to a computer storage product with a computer- or processor-readable medium (also can be referred to as a processor-readable medium) having instructions or computer code thereon for performing various computer-implemented operations. The media and computer code (also can be referred to as code) may be those designed and constructed for the specific purpose or purposes. Examples of computer-readable media include, but are not limited to: magnetic storage media such as hard disks, floppy disks, and magnetic tape; optical storage media such as Compact Disc/Digital Video Discs (CD/DVDs), Compact Disc-Read Only Memories (CD-ROMs), and holographic devices; magneto-optical storage media such as optical disks; carrier wave signal processing modules; and hardware devices that are specially configured to store and execute program code, such as general purpose microprocessors, microcontrollers, Application-Specific Integrated Circuits (ASICs), Programmable Logic Devices (PLDs), and Read-Only Memory (ROM) and Random-Access Memory (RAM) devices.

Examples of computer code include, but are not limited to, micro-code or micro-instructions, machine instructions, such as produced by a compiler, code used to produce a web service, and files containing higher-level instructions that are executed by a computer using an interpreter. For example, embodiments may be implemented using Java, C++, or other programming languages (e.g., object-oriented programming languages) and development tools. Additional examples of computer code include, but are not limited to, control signals, encrypted code, and compressed code.

Although various embodiments have been described as having particular features and/or combinations of components, other embodiments are possible having a combination of any features and/or components from any of embodiments where appropriate. For example, while shown above as being coupled to a single switch fabric, the edge devices shown and described herein can be coupled to any number of switch fabrics and/or modules associated with a first stage of a switch fabric. In some embodiments, for example, the edge devices

are coupled to two switch fabrics. In other embodiments, the edge devices are coupled to more than two switch fabrics.

What is claimed is:

1. A method, comprising:

receiving a first data packet from a first peripheral device including a first data packet header specifying a destination;

appending, at a first edge device, a destination identifier to the first data packet based on the first data packet header to define a first appended data packet, the destination identifier associated with a destination port of a second edge device;

sending the first appended data packet to a module associated with a first stage of a switch fabric based on the first data packet header such that the module associated with the first stage of the switch fabric sends the first appended data packet to a module associated with the second stage of the switch fabric based on the destination identifier, the module associated with the first stage of the switch fabric being from a plurality of modules associated with the first stage of the switch fabric, the module associated with the second stage of the switch fabric being from a plurality of modules associated with the second stage of the switch fabric;

receiving a second data packet including a second data packet header specifying the destination; and

appending, at the first edge device, the destination identifier to the second data packet based on the second data packet header to define a second appended data packet.

2. The method of claim **1**, wherein the first appended data packet sent to the module associated with the first stage of the switch fabric is sent such that the first stage of the switch fabric sends the first appended data packet to the module associated with the second stage of the switch fabric without the first stage of the switch fabric directly associating the destination identifier with an address of the second edge device.

3. The method of claim **1**, wherein the first appended data packet sent to the module associated with the first stage of the switch fabric is sent such that the first stage of the switch fabric sends the first appended data packet to the module associated with the second stage of the switch fabric without the first stage of the switch fabric parsing the first data packet header.

4. The method of claim **1**, wherein the first appended data packet sent to the module associated with the first stage of the switch packet is sent such that the module associated with the second stage of the switch fabric sends the first appended data packet to a module associated with a third stage of the switch fabric based on the destination identifier, the module associated with the third stage of the switch fabric being from a plurality of modules associated with the third stage of the switch fabric.

5. The method of claim **4**, further comprising:

sending the second appended data packet to the module associated with the first stage of the switch fabric such that the module associated with the first stage of the switch fabric sends the second appended data packet to the module associated with the second stage of the switch fabric based on the destination identifier and such that the module associated with the second stage of the switch fabric sends the second appended data packet to the module associated with the third stage of the switch fabric based on the destination identifier.

6. The method of claim **4**, wherein any data packet having the destination identifier at the first edge device is sent to the module associated with the first stage of the switch fabric, the module associated with the second stage of the switch fabric, and the module associated with the third stage of the switch fabric, the method further comprising:

assigning the destination identifier based on a result of a hash function using as input at least one field from the first data packet header, the at least one field from the first data packet header being at least one of a destination MAC address, a destination IP address, a source MAC address, a source IP address, or a transfer protocol.

7. The method of claim **1**., wherein the destination is a first destination, the destination identifier is a first destination identifier, and the module associated with the first stage of the switch fabric is a first module associated with the first stage of the switch fabric, and the module associated with the second stage is a first module associated with the second stage of the switch fabric, the method further comprising:

sending the second appended data packet to the first module associated with the first stage of the switch fabric such that the first module associated with the first stage of the switch fabric sends the second appended data packet to the first module associated with the second stage of the switch fabric based on the first destination identifier;

receiving a third data packet including a third data packet header specifying a second destination;

appending, at the first edge device, a second destination identifier to the third data packet based on the third data packet header to define a third appended data packet;

sending the third appended data packet to a second module associated with the first stage of the switch fabric such that the second module associated with the first stage of the switch fabric sends the third appended data packet to a second module associated with the second stage of the switch fabric based on the second destination identifier.

8. A non-transitory processor readable medium storing code representing instructions to be executed by a processor, the code comprising code to cause the processor to:

receive, from an edge device, a first data packet including a first header and a second header, the second header having been appended to the first data packet by the edge device based on the first header;

send the first data packet to a module associated with a stage of a switch fabric based on the second header such that the first data packet is routed to a peripheral device, at least a portion of a route to the peripheral device after the stage of the switch fabric determined based on the second header, the module associated with the stage of the switch fabric being from a plurality of modules associated with the stage of the switch fabric; and

receive, from the edge device, a second data packet including a third header and a fourth header, the fourth header, having been appended to the second data packet b the edge device based on the third header such that the second data packet is routed to the peripheral device via the module, associated with the stage of the switch fabric and the portion of the route after the stage of the switch fabric.

9. The non-transitory processor readable medium of claim **8**, wherein the code to cause the processor to send the first data packet based on the second header causes the first data packet to be sent without parsing the first header.

10. The non-transitory processor readable medium of claim **8**, wherein the processor is a processor of a module of a second stage of a switch fabric such that the first data packet is received from the edge device via a module of a first stage of the switch fabric.

11. The non-transitory processor readable medium of claim 8, wherein:

the processor is a processor of a module of a first stage of a switch fabric;

the code to cause the processor to send the first data packet is code to send the first data packet to a module of a second stage of a switch fabric; and

a route from the module of the second stage of the switch fabric to a module of a third stage of the switch fabric is determined based on the second header.

12. A method, comprising:

assigning a destination port of an output module to a first data packet based on at least one field in a first header of the first data packet;

selecting a module associated with a first stage of a switch fabric based on at least one field in the first header, the module associated with the first stage being from a plurality of modules associated with the first stage;

appending a second header to the first data packet to define a first appended data packet, the second header including an identifier associated with the destination port of the output module;

sending the first appended data packet to the module associated with the first stage, the module associated with the first stage configured to send the first appended data packet to a module associated with a second stage of the switch fabric based on the second header, the module associated with the second stage being from a plurality of modules associated with the second stage;

appending the second header to a second data packet to define a second appended data packet based on a first header of the second data packet having t e at least one field of the first header of the first data packet, and such the second appended data packet is routed to the module associated with the second stage of the switch fabric.

13. The method of claim 12, wherein the selecting the module associated with the first stage includes selecting the module associated with the first stage based on at least one of a destination MAC address, a destination IP address, a source MAC address, a source IP address, or a transfer protocol.

14. The method of claim 12, wherein the switch fabric includes at least three stages.

15. The method of claim 12, wherein the selecting the module associated with the first stage includes selecting the module associated with the first stage based on a result of a hash function using as input at least one of a destination MAC address, a destination IP address, a source MAC address, a source IP address, or a transfer protocol.

16. The method of claim 12, wherein the module associated with the first stage is configured to select the module associated with the second stage based on a result of a hash function using as an input the identifier associated with the destination port of the output module.

17. The method of claim 12, wherein the second header of the second data packet includes an identifier associated with the destination port of the output module, the method further comprising:

assigning the destination port of the output module to the second data packet based on at least one field in the first header of the second data packet;

selecting the module associated with the first stage of the switch fabric based on at least one of the fields in the first header of the second data packet; and

sending the second appended data packet to the module associated with the first stage, the module associated with the first stage configured to send the second appended data packet to the module associated with the second stage of the switch fabric based on the second header of the second appended data packet.

18. The method of claim 12, wherein the assigning includes assigning the destination port of the first output module based on a MAC address of a server operatively coupled to the destination port of the first output module.

19. The method of claim 12, wherein the sending the first appended data packet includes sending (1) a data portion of the first appended data packet, (2) the first header, and (3) the second header to the module associated with the first stage.
